Abstract. In the research project NAVIO (Pedestrian Navigation Systems in Combined Indoor/Outdoor Environments) at our University we are working on the improvement of navigation services for pedestrians. Thereby we are mainly focusing on the information aspect of location-based services, i.e., on the user's task at hand and the support of the user's decisions by information provided by such a service. Specifications will allow us to select appropriate sensor data and to integrate data when and where needed, to propose context-dependent routes fitting to partly conflicting interests and goals as well as to select appropriate communication methods in terms of supporting the user guidance by various multimedia cartography forms. These tasks are addressed in the project in three different work packages, i.e., the first on "Integrated positioning", the second on "Pedestrian route modeling" and the third on "Multimedia route communication". In this paper we will concentrate on the research work and findings in the first work package. For continuous positioning of a pedestrian suitable location technologies include GNSS and indoor location techniques, cellular phone positioning, dead reckoning sensors (e.g. magnetic compass, gyro and accelerometers) for measurement of heading and travelled distance as well as barometric pressure sensors for height determination. The integration of these sensors in a modern multi-sensor system can be performed using an adapted Kalman filter. To test and to demonstrate our approach, we take a use case scenario into account, i.e., the guidance of visitors to departments of the Vienna University of Technology. The results of simulation studies and practical tests could confirm that such a service can achieve a high level of performance for the guidance of a pedestrian in urban areas and mixed indoor and outdoor environments.

Key words: Pedestrian navigation, Location-based services, Multi-sensor systems, Integrated positioning, Indoor location

1 Introduction

Pedestrian navigation services require continuous positioning and tracking of a mobile user with a certain positioning accuracy and reliability. Especially navigating in urban environments and mixed indoor and outdoor areas is a very challenging task as pedestrians move in spaces where no one of the known location methods works continuously in standalone mode. A solution of the problem can only be found if different location technologies are combined in the sense of a modern multi-sensor system. In this paper suitable location technologies for pedestrian navigation are identified and investigated. These technologies include GNSS and indoor location services as well as cellular phone positioning for absolute position determination; dead reckoning sensors (e.g. magnetic compass, gyros and accelerometers) for measurement of orientation and travelled distance from a known start position as well as barometric pressure sensors for height determination. For location determination of a pedestrian in a multi-storey building the use of WLAN (Wireless Local Area Networks) is investigated. To achieve an integrated positioning determination with other sensors and a seamless transition between indoor and outdoor areas, a multi-sensor fusion model based on an extended Kalman filter approach is employed. Finally, in a practical use case scenario the guidance of a pedestrian from public transport stops to our Department of the Vienna University of Technology is investigated. The results of this study showed that such a pedestrian navigation service can achieve a high level of performance.

2 Integrated positioning in navigation services

A reliable pedestrian navigation services requires the determination of the current user's position using different sensors that are integrated into the system design. In the work package "Integrated positioning" of

the research project NAVIO (Pedestrian Navigation Systems in Combined Indoor/Outdoor Environments) the following challenging tasks are addressed:

- The capability to track the movements of a pedestrian in real-time using different suitable location sensors and to obtain an optimal estimate of the current user's position.
- The possibility to locate the user in 3 dimensions with high precision (that includes to be able to determine the correct floor of the user in a multi-storey building).
- The capability to achieve a seamless transition for continuous positioning determination between indoor and outdoor areas.

Thereby a navigation support must be able to provide location, orientation and movement of the user as well as related geographic information matching well with the real world situation experienced by pedestrians. The integration of the sensors in a modern multi-sensor system can be performed using a Kalman filter as this algorithm is particularly suited for real-time evaluation. In the following the state-of-the-art in mobile positioning is discussed and suitable sensors for integrated positioning in a pedestrian navigation service are identified.

2.1 State-of-the-art in mobile positioning

Satellite-positioning technologies (GNSS) are employed most commonly for outdoor navigation. Then the achievable positioning accuracies of the navigation system are on the few meters to 10 m level in standalone mode or sub-meter to a few meter level in differential mode (e.g. DGPS). If an insufficient number of satellites is available for a short period of time due to obstructions, then in a conventional approach observations of additional sensors are employed to bridge the loss of lock of satellite signals. For pedestrian navigation, sensors such as a low-cost attitude sensor (digital compass) giving the orientation and heading of the person being navigated and a digital step counter or accelerometers for travel distance measurements can be employed. Using these sensors, however, only relative position determination from a known start position (also referred to as Dead Reckoning DR) is possible and the achievable accuracy depends on the type of movement tracking sensors used and the position prediction algorithm adopted.

For indoor positioning different techniques have been developed. They offer either absolute or relative positioning capabilities. Some of them are based on short-range or mid-range technologies using sensors such as transponders or beacons installed in the building (see e.g. Klinec and Volz, 2000; Pahlavan *et al.*, 2002). An

example are the so-called Local Positioning Systems (LPS) that have an operation principle similar to GNSS. The LPS systems claim to achieve a distance measurement accuracy of about 0.3 to 1 m (see e.g. Werb and Lanz, 2000; Sypniewski, 2000), but no details are given on the test results and the achievable accuracy on position fixing. Other indoor positioning systems include so-called Active Badge or Active Bats Systems (Hightower and Boriello, 2001). These systems are mainly employed for the location of people and finding things in buildings. Also WLAN (Wireless Local Area Networks) can be employed for location determination. In this case, the signal strength of the radio signals from at least one WLAN access point installed in the building is measured. The location fix is then obtained with triangulation using measurements to several access points or through comparison with in database stored signal strength values from calibrated points (this method is also referred to as fingerprinting). Further information can be found in e.g. (Bastisch *et al.*, 2003; Beal, 2003; Imst, 2004; Retscher 2004b). As the indoor radio channel suffers from severe multipath propagation and heavy shadow fading, the fingerprint method provides higher accuracies than triangulation. It is reported that positioning accuracies of about 1 to 3 m could be obtained in a test office building using the fingerprint WLAN positioning method (Imst, 2004). Another alternative in indoor geolocation applications is the use of ultra wideband (UWB) systems, which exploit bandwidths in excess of 1 GHz, to measure accurate time of arrival (ToA) of the received signals for estimation of distance (Pahlavan *et al.*, 2002). With results of propagation measurement in a typical modern office building, it has been shown that the UWB signal does not suffer multipath fading (Win and Scholtz, 1998), which is desirable for accurate ToA estimation in indoor areas. The main disadvantage, however, is the possible interference of UWB devices with the GPS system. Also Bluetooth, which has been originally developed for short range wireless communication, can be employed for locating mobile devices in a certain cell area that is represented by the range of the device which is typically less than 10 m. It can be employed for location determination using active landmarks. Locating the user on the correct floor of a multistory building is another challenging task. For more accurate determination of the user's position in vertical dimension an improvement can be achieved employing a barometric pressure sensor or digital altimeter additionally (see Retscher and Skolaut, 2003).

As an alternative for location determination in indoor and outdoor environments, mobile positioning services using cellular phones can be employed. Apart from describing the location of the user using the cell of the wireless network, more advanced positioning methods have been developed. Most of them are based on classical terrestrial

navigation methods where at least two observations are required to obtain a 2-D position fix (see e.g. Balbach, 2000; CPS, 2001; Drane *et al.*, 1998; Hein *et al.*, 2000; Retscher, 2002). The achievable positioning accuracy thereby depends mainly on the location method and type of wireless network (GSM, W-CDMA, UMTS). As advanced and more accurate methods, such as the E-OTD (Enhanced Observed Time Difference) method, require modification of the network as well as installation of additional hardware in the network and reference stations which are called LMU's (Location Measurement Units), they have not been widely deployed yet. Recent developments have therefore been concentrated on the reduction of network modification. The so-called Matrix method (see Duffett-Smith and Craig, 2004) does not need any additional hardware in the network apart from a SMLC (Serving Mobile Location Centre) where the location determination of the mobile handset is performed. Using this method positioning accuracies of 50 to 100 m at the 67 % reliability level can be achieved in the GSM network.

2.2 Suitable sensors for pedestrian navigation services

Suitable sensors and location techniques for pedestrian navigation have been identified at the start of the project

NAVIO. Table 1 gives an overview about the positioning methods and the sensors that will be employed in our project. For absolute position determination primarily GNSS is employed. In the case of no GNSS availability it can be replaced by location techniques using cellular phones or indoor positioning systems (e.g. WLAN positioning). Apart from these sensors, relative DR (Dead Reckoning) sensors are employed for the observation of the travelled distance (from velocity and acceleration measurements), direction of motion or heading and height difference. The observables as well as their accuracies are summarized in Table 1.

2.3 Integrated positioning using a multi-sensor fusion model

An integrated position determination, using observations of all available sensors, however, is not performed in most common navigation systems. In vehicle navigation systems for instance the resulting trajectory is determined mainly based on the dead reckoning observations; GNSS is used for updating and resolving the systematic error growth of the DR observations. For guidance of a pedestrian in 3-D space and updating of his route, continuous position determination is required with

Method	Sensor	Observations	Accuracy
GNSS	e.g. Garmin GPS 35 DGPS	y, x, z	6-10 m 1-4 m
Indoor Positioning	e.g. WLAN Positioning IMST ipos	y, x, z	1-3 m
Cellular Phone Positioning	GSM (e.g. Matrix method)	y, x	50-100 m
Dead Reckoning	e.g. PointResearch DRM-III Dead Reckoning Module	y, x z φ	20-50 m per 1 km 3 m 1°
Direction of Motion (Heading)	e.g. Honeywell Digital Compass Module HMR 3000	φ	0.5°
Acceleration	e.g. Crossbow Accelerometer CXTD02	a_{tan}, a_{rad}, a_z	$> 0.03 \text{ ms}^{-2}$
Velocity from GNSS	e.g. Garmin GPS 35	v_y, v_x v_z	$\sim 0,05 \text{ m}^{-1}$ $\sim 0,2 \text{ m}^{-1}$
Barometer	e.g. Vaisala Pressure sensor PTB220A	z	1-3 m

Tab. 1 Sensors for pedestrian navigation services with their observables and accuracies

(Garmin, 2004; Imst, 2004; Duffett-Smith and Craig, 2004; PointResearch, 2004; Honeywell, 2004; Crossbow, 2004; Vaisala, 2004)

where y, x, z are the 3-D coordinates of the current position, v_y, v_x, v_z are the 3-D velocities, φ is the direction of motion (heading) in the ground plane xy , a_{tan} is the tangential acceleration and a_{rad} is the radial acceleration in the ground plane xy , a_z is the acceleration in height (z coordinate)

positioning accuracies on the few meter level or even higher, especially for navigation in multi-storey buildings in vertical dimension (height) as the user must be located on the correct floor. The specialized research hypothesis of this work package in the project NAVIO is that a mathematical model for integrated positioning can be developed that provides the user with a continuous navigation support. Therefore appropriate location sensors have to be combined and integrated using a new multi-sensor fusion model. A Kalman filter approach is particularly suited for the integration and sensor fusion in real-time. Extending basic filter concepts, a Kalman filter approach which integrates all observations from the different sensors will be developed. The model must be able to make full use of all available single observations of the sensors at a certain time to obtain an optimal estimate of the current user state (i.e., position, orientation and motion). For further information on the multi-sensor fusion model the reader is referred to Retscher and Mok (2004) and Retscher (2004b).

3. Practical sensor tests

Practical tests in our research project are carried out for the guidance of visitors of the Vienna University of Technology to certain offices in different buildings or to certain persons. Thereby we assume that the visitor employs a pedestrian navigation system using different sensors that perform an integrated positioning. Start points are nearby public transport stops, e.g. underground stop Karlsplatz in the center of Vienna or railway station Südbahnhof near our university. In the following, results of satellite positioning and first test measurements with the Dead Reckoning Module DRM III from Point Research are presented.

3.1 Satellite positioning test results

Figure 1 shows the GPS measurements for the path from the underground stop Karlsplatz near our University to our Institute building of the Vienna University of Technology in the Gusshausstrasse located in the fourth district of the city of Vienna using two different GPS receivers, i.e., the Trimble GPS Pathfinder Pocket and the Garmin eTrex. The length of the path is approximately 500 m and it starts at the exit of underground station Karlsplatz where open skies provide free satellite visibility. Then the pedestrian walks through a park (i.e., the Resselpark) with trees where satellite signals are frequently blocked over short periods. Both GPS receivers, however, are able to determine the track of the pedestrian with a reasonable positioning accuracy. It can be seen, that the track of the Garmin eTrex receiver is much smoother as he performs some filtering or

smoothing to estimate the receiver track compared to the Trimble GPS Pathfinder Pocket which provides the original GPS single point positions. After leaving the park, the path continues in a narrow street (i.e., Karlsgasse) onwards to our Institute building where 5-storey buildings with heights of typically 20 m cause obstructions of the satellite signals. The measurement result from the Garmin eTrex shows an increasing deviation from the true pedestrian path where the maximum deviation in the range of 13 m is reached at the intersection of Karlsgasse with Frankenberggasse. Then the position changes quite significantly as more GPS satellites become available. In the following, the positions show again a drift from the true path. As the Trimble GPS Pathfinder Pocket receiver does not apply any filtering or smoothing, the positions in the Karlsgasse are much more scattered than with the Garmin eTrex. Maximum deviations from the true path of the pedestrian of up to 25 m are reached and in some parts no position determination is possible. These gaps have to be bridged using dead reckoning observations. At the intersection of Karlsgasse with Gusshausstrasse enough satellites are visible for positioning and the path ends in front of the building where our Institute is located.

3.2 Dead reckoning test results

For the measurements the Dead Reckoning Module DRM III from Point Research (PointResearch, 2004) was employed. The system is a self contained navigation unit where GPS is not required for operation. It provides independent position information based on the user's stride and pace count, magnetic north and barometric altitude. The module is designed to self-calibrate when used in conjunction with an appropriate GPS receiver, and can produce reliable position data during GPS outages. The system consists of an integrated 12 channel GPS receiver, antenna, digital compass, pedometer and altimeter. The module is clipped onto the user's belt in the middle of the back and the GPS antenna may be attached to a hat. Firmware converts the sensor signals to appropriate discrete parameters, calculates compass azimuth, detects footsteps, calculates altitude and performs dead reckoning position calculation. A Kalman filter algorithm is used to combine dead reckoning position with GPS position to obtain an optimum estimate for the current user's position and track. With the dead reckoning module and GPS integrated together, a clear view of the sky is only required for obtaining the initial position fix. The fix must produce an estimated position error of 100 m or less to begin initialization. Subsequent fixes use both dead reckoning and GPS data, so obstructed satellites are not as critical as in a GPS only configuration. The Kalman filter continuously updates calibration factors for stride length and compass mounting

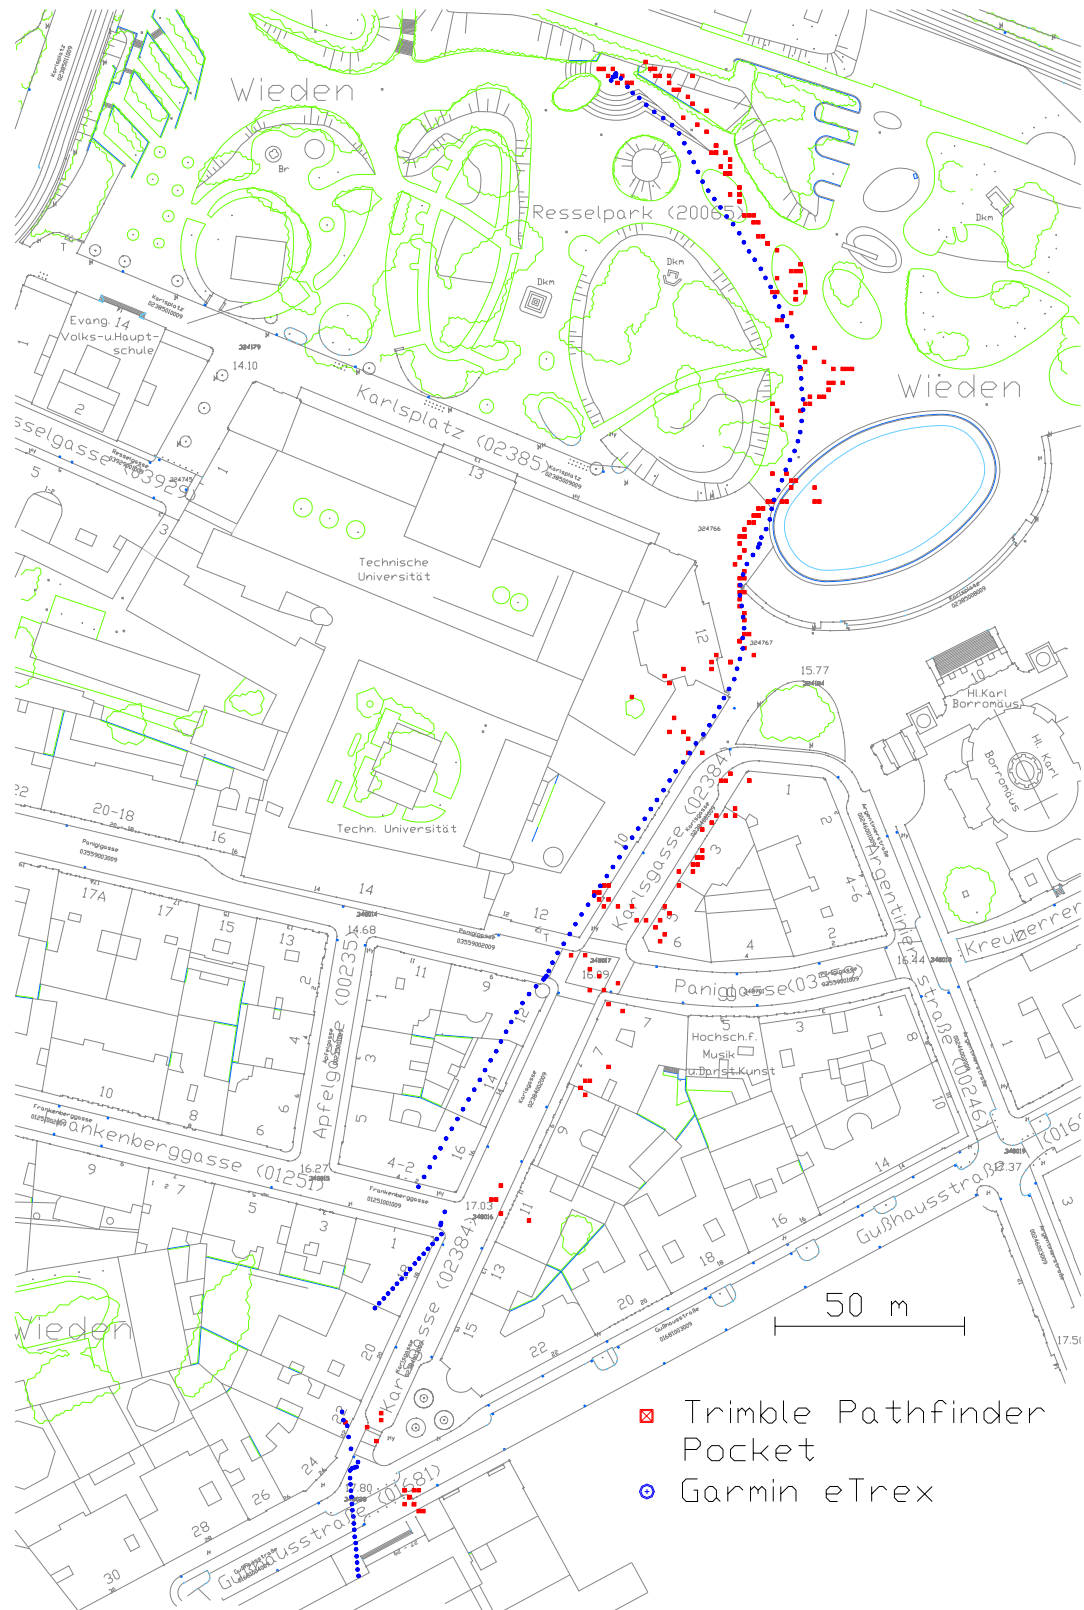

Fig. 1 GPS measurements for the pedestrian path from the underground station Karlsplatz to our office building of the Vienna University of Technology

offset. The GPS position error must be less than 30 m before GPS data will be used by the Kalman filter, and the first such fix will also initialize the module's latitude and longitude. Subsequently, the filter will use any GPS position fix with an estimated position error of 100 m or less, adjusting stride, body offset, northing, easting, latitude and longitude continually.

First of all the Dead Reckoning Module DRM III was tested in open area with GPS satellite visibility. As test site pedestrian paths in the park of Schönbrunn Palace in Vienna have been chosen. Figure 2 shows the trajectory of the pedestrian as well as GPS and two different dead reckoning measurements. For the dead reckoning measurements the GPS positioning and the calibration of the stride length using the Kalman filter algorithm was deactivated. Without using the filter, GPS measurements are not employed to calibrate the stride length and the dead reckoning module uses the preset value of 800 mm for the stride length. The heading of the user is determined from measurements of a digital compass and a gyro. For the first dead reckoning measurement (No. 1)

shown in Figure 2 both sensors are employed to obtain the heading, for the second measurement (No. 2) only the observations of the compass are employed. This results in larger deviations from the trajectory for the second dead reckoning measurements; they range from 17 m over a distance of 150 m and 29 m over 200 m. For the first dead reckoning measurement the deviations from the trajectory are in the range of 7 m over a distance of 150 m and 20 m over 200 m. It can therefore be recommended that a combination of compass and gyro measurements are employed for heading observation. An improvement of the dead reckoning measurements can only be achieved if the calibration of the stride length is employed to obtain a better estimate for the travelled distance. For comparison, GPS measurements from the internal receiver of the DRM III module are shown in Figure 2 which reach a maximum deviation of 7 m from the trajectory.

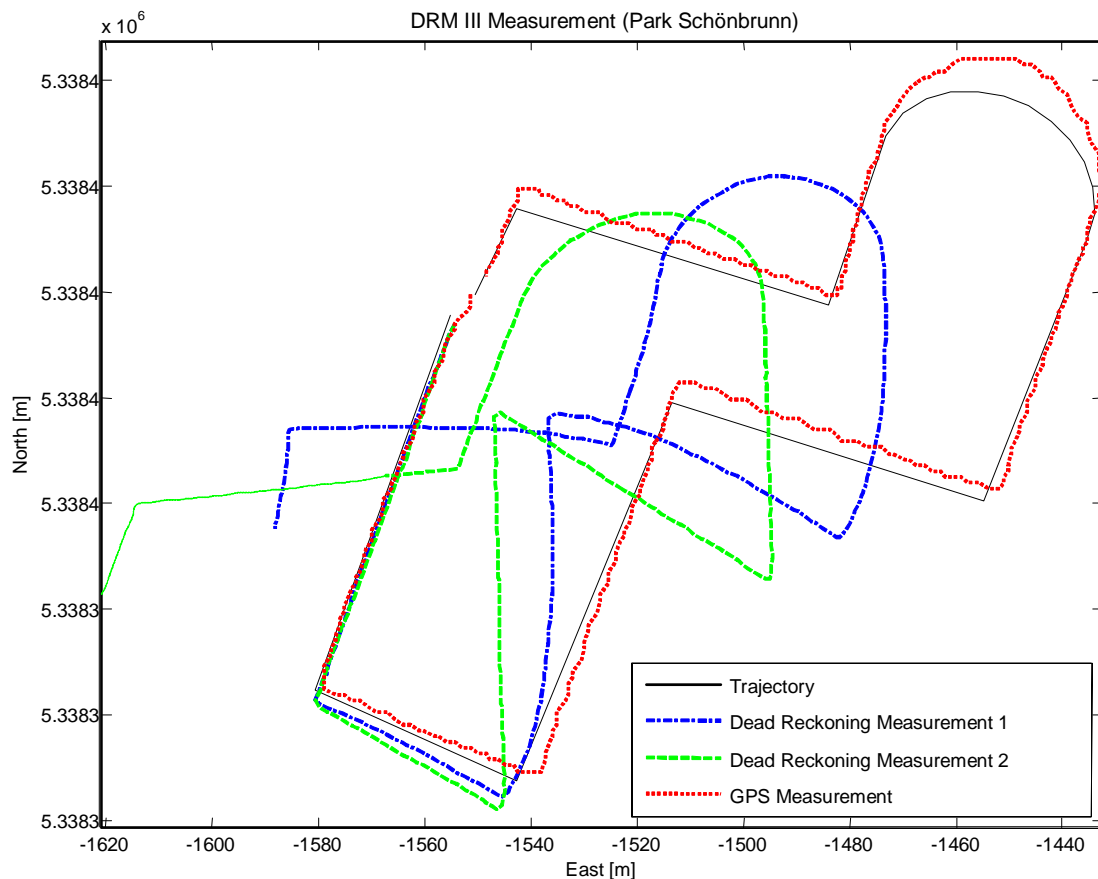

Fig. 2 Test measurements with the Dead Reckoning Module DRM III in the park of Schönbrunn Palace in Vienna

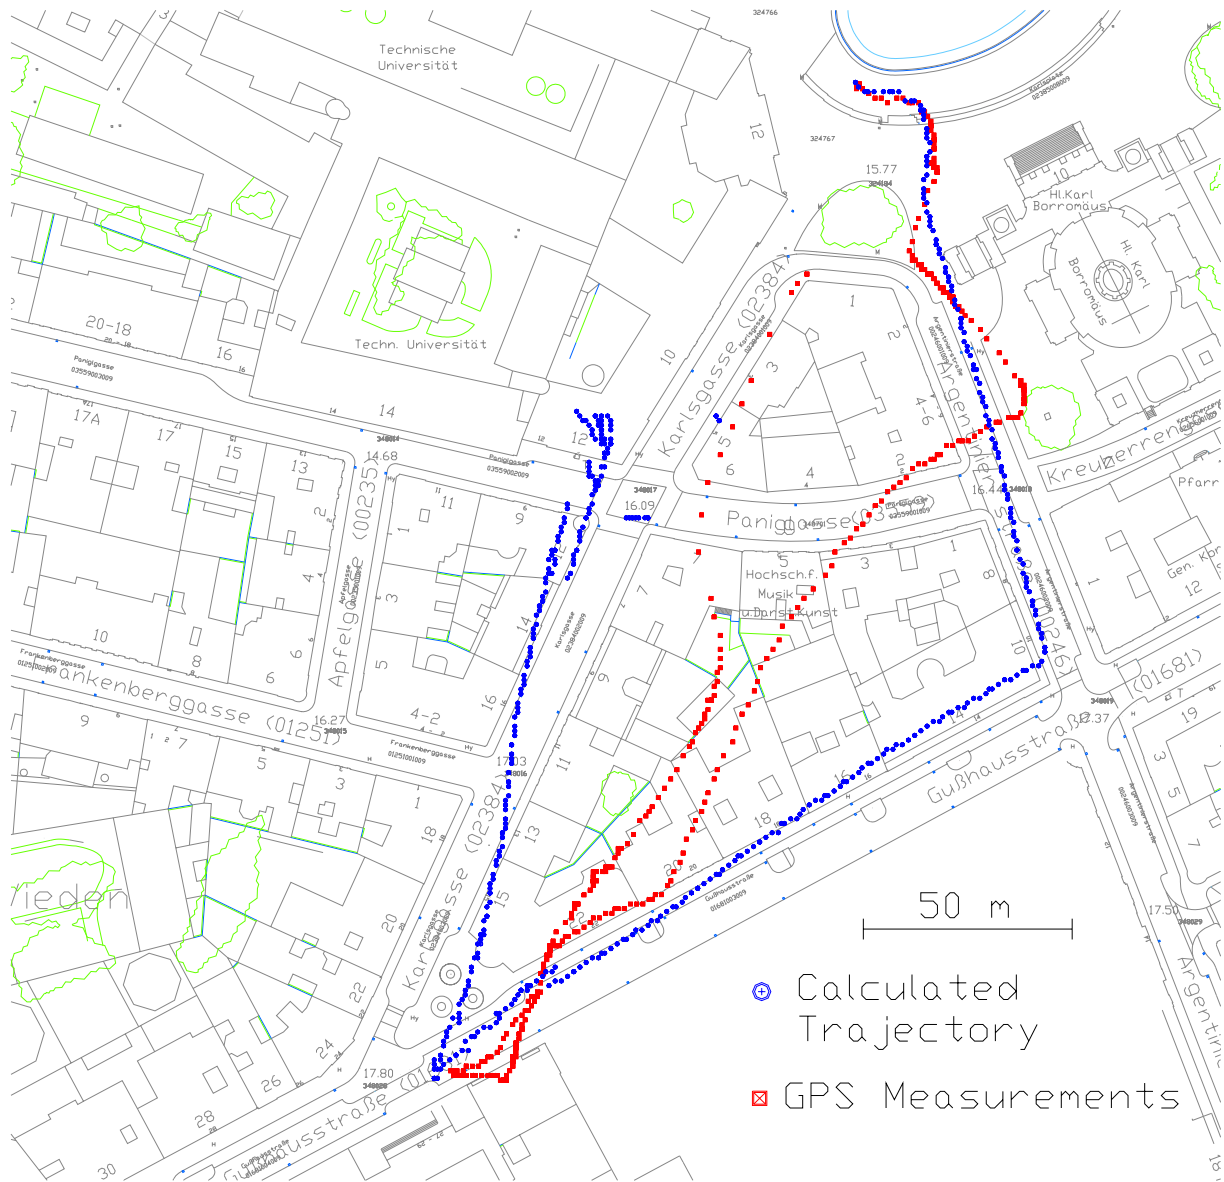

Fig. 3 Test measurements with the Dead Reckoning Module DRM III along a closed loop on narrow streets in the city Vienna

Figure 3 shows the measurement results of the DRM III dead reckoning module and GPS single point positions on a closed loop in the city of Vienna starting from the Resselpark about 160 m along Argentinierstrasse, then 200 m along Gusshausstrasse and 290 m along Karlgasse back to the start point. The total length of the path is around 550 m. The streets are quite narrow with 5-storey buildings with an average height over 20 m causing frequent obstructions of the satellite signals and high GDOP values. As can be seen in Figure 3, the GPS only measurements are quite far away from the true path of the pedestrian along most parts of the track and a reliable match to the correct street would not always be possible. Using the position estimates of the dead reckoning module the resulting trajectory follows the pedestrian

track along the most part of path and the deviations are only in the range of a few meters. Due to the large errors of the GPS positions, however, the calibration algorithm of the DRM III fails at the end and the resulting trajectory cannot follow the track of the pedestrian any more. Figure 4 shows the calibration of the stride length in the Kalman filter and it can be seen that the stride length gets smaller and smaller until it reaches nearly 500 mm which is not a matter of fact. In this case, it seems that the weighting of GPS positioning is too high in the Kalman filter calibration process for the stride length.

In our project, an improvement of the current position estimate of a pedestrian using observations of different dead reckoning sensors in combination with GPS and other absolute positioning techniques (see Table 1) should

be achieved using a new multi-sensor fusion model based on an extended Kalman filter approach. Further

information about this approach can be found in Retscher and Mok (2004) and Retscher (2004b).

4. Conclusions

In the NAVIO project major aspects being important when conceiving a pedestrian navigation service are investigated, i.e., integrated positioning, multi-criteria route planning, and multimedia route communication (see Gartner *et al.*, 2004a and b). As a result, a specific pedestrian navigation service as use case will derive the requirements on positioning, route planning, and communication. A prototype of the service will guide visitors of the Vienna University of Technology to departments and persons. Practical tests will allow us to evaluate and demonstrate the usability of the service, and thus, prove the projects attempts.

With the work package “Integrated Positioning” of the project we will contribute to the integration of location sensors in the sense of a multi-sensor system to achieve a continuous positioning of the user of the service and a seamless transition between indoor and outdoor areas. Suitable sensors and location methods have been identified and the basic concept of a multi-sensor fusion

model for integrated positioning has been developed (Retscher and Mok, 2004; Retscher 2004b). Special emphasis has been given on the location determination and navigation of a pedestrian in a multi-storey building. Currently we are investigating the use of WLAN positioning for location determination in indoor areas.

The second work package of the project NAVIO on “Pedestrian route modeling” is dealing with the ontological modelling of navigation tasks, deriving well founded criteria and optimization strategies in route selection; and the third work package on “Multimedia route communication” is working on models for context-dependent communication modes of route information. In general, it can be said that the results of the project NAVIO will contribute to the improvement of modern (pedestrian) navigation services.
